## ABSTRACT

We describe a long term project aimed at deriving information on the chemical evolution of the Galactic disk from a large sample of open clusters. The main property of this project is that all clusters are analyzed in a homogeneous way, to guarantee the robustness of the ranking in age, distance and metallicity. Special emphasis is devoted to the evolution of the earliest phases of the Galactic disk evolution, where clusters have superior reliability with respect to other types of evolution indicators. The project is twofold: on the one hand we derive age, distance and reddening (and indicative metallicity) interpreting deep and accurate photometric data with stellar evolution models, and, on the other hand, we derive the chemical abundances from high-resolution spectroscopy. Here we describe our overall goals and approaches, and report on the mid-term project status of the photometric part, with 16 clusters already studied, covering an age interval from 0.1 to 6 Gyr and Galactocentric distances from 6.6 to 21 kpc. The importance of quantifying the theoretical uncertainties by deriving the cluster parameters with various sets of stellar models is emphasized. Stellar evolution models assuming overshooting from convective regions appear to better reproduce the photometric properties of the cluster stars.

The examined clusters show a clear metallicity dependence on the Galactocentric distance and no dependence on age. The tight relation between cluster age and magnitude difference between the main sequence turn off and the red clump is confirmed.

*Subject headings:* Galaxy: evolution – Galaxy: disk – Open clusters and associations: general – Hertzsprung-Russell (HR) diagram

## 1. Introduction

In the last decade, our understanding of the chemical evolution of the Galaxy has significantly improved, thanks to the efforts and the achievements both on the observational and on the theoretical sides. Numerical chemical evolution models nowadays can satisfactorily reproduce the major observed features of the Milky Way (e.g. Lacey & Fall 1985, Tosi 1988, Matteucci & François 1989, Ferrini et al. 1994, Giovagnoli & Tosi 1995, Timmes, Woosley & Weaver 1995, Chiappini, Matteucci & Gratton 1997, Boissier & Prantzos 1999). They are considered successful only when they reproduce the current distribution with Galactocentric distance of the SFR (e.g. as com-

piled by Lacey & Fall 1985), the current distribution with Galactocentric distance of the gas and star densities (see e.g. Tosi 1996, Boissier & Prantzos 1999 and references therein); the current distribution with Galactocentric distance of element abundances as derived from HII regions and from B-stars (e.g. Shaver et al. 1983, Smartt & Rolleston 1997); the distribution with Galactocentric distance of element abundances at slightly older epochs, as derived from PNe II (e.g. Pasquali & Perinotto 1993, Maciel & Chiappini 1994, Maciel & Köppen 1994, Maciel, Costa & Uchida al. 2003); the age-metallicity relation (AMR) not only in the solar neighborhood (Twarog 1980) but also at other distances from the Galactic center (e.g. Edvardsson et al. 1993); the metallicity

distribution of G-dwarfs in the solar neighborhood (e.g. Rocha-Pinto & Maciel 1996); the local Present-Day-Mass-Function (PDMF, e.g. Scalo 1986, Kroupa, Tout & Gilmore 1993); the relative abundance ratios (e.g.  $[O/Fe]$  vs  $[Fe/H]$ ) in disk and halo stars (e.g. Barbuy 1988, Edvardsson et al. 1993).

There are, however, several open questions which still need to be answered. One of the important longstanding questions concerns the evolution of the chemical abundance gradients in the Galactic disk. The distribution of heavy elements with Galactocentric distance, as derived from young objects like HII regions or B stars, shows a trend in the disk of the Galaxy and of other well studied spirals which is usually interpreted as a linear negative gradient. It is not clear yet whether the gradient slope changes with space and time, and, in case, if it flattens or steepens.

Galactic chemical evolution models do not provide a consistent answer: even those that are able to reproduce equally well the largest set of observational constraints predict different scenarios for early epochs. By comparing with each other the most representative models of the time, Tosi (1996) showed that the predictions on the gradient evolution range from a slope initially positive which then becomes negative and steepens with time, to a slope initially negative which remains roughly constant, to a slope initially negative and steep which gradually flattens with time (see also Tosi 2000 and Chiappini, Matteucci & Romano 2001 for updated discussions and references).

From the observational point of view, the situation is not much clearer. Data on field stars are inconclusive, due to the large uncertainties affecting the older, metal poorer ones. Planetary nebulae (PNe) are better indicators, thanks to their brightness. PNe of type II, whose progenitors are on average 2–3 Gyr old, provide information on the Galactic gradient at that epoch and show gradients similar to those derived from HII regions. However, the precise slope of the radial abundance distribution, and therefore its possible variation with time is still subject of debate. The PNe data of Pasquali & Perinotto (1993), Maciel & Chiappini (1994) and Maciel & Köppen (1994) showed gradient slopes slightly flatter than those derived from HII regions, but Maciel et al. (2003) and Maciel, Lago & Costa (2005) have recently inferred,

from a larger and updated PN data set, a flattening of the oxygen gradient slope during the last 5–9 Gyr.

We believe that open clusters (OCs) represent the best tool to understand whether and how the metallicity spatial distribution changes with time, since they have formed at all epochs and their ages, distances and metallicities are more safely derivable than for field stars. OCs have generally been suggested to show a metallicity gradient (e.g., Janes 1979, Panagia & Tosi 1981, Friel 1995, Carraro, Ng & Portinari 1998, Friel et al. 2002), and Maciel et al. (2005) have recently suggested that OC literature data are consistent with those on PNe in the indication of a time flattening of the gradient. However, the spatial and temporal evolutions of the metallicity distribution of OCs are still uncertain.

Bragaglia et al. (2000) using the compilation of ages, distances and metallicities listed by Friel (1995), and dividing her clusters in four age bins, found no significant variation in time of the gradient slope. This, however, more than reflecting the Galaxy evolution, may be an effect of inhomogeneity in the data treatment of clusters taken from different literature sources. Carraro et al. (1998), using the metallicities of 37 OCs derived by Friel’s group from low resolution spectra, and age and distances based on their own synthetic color-magnitude diagrams (CMDs), tried to measure the time dependence of the radial metallicity gradient. They found hints that the gradient may be slightly shallower at the present time than in the past, but, again, the results may be affected by uncertainties related to the uneven quality of the literature data they applied the synthetic CMD method to. Similarly, Friel et al. (2002) presented new, improved data on the metallicity of 39 OCs, and derived a smooth radial gradient, with indication that its slope may be steeper for old clusters, but do not consider this a firm result, due to the different space distribution of young and old OCs.

Against the view of an OC’s radial abundance gradient, Twarog, Ashman, & Anthony-Twarog (1997), and more recently Corder & Twarog (2001), argue that what is observed is a step distribution in OC metallicity, rather than a smooth gradient: clusters with  $R_{GC} \leq 10$  kpc have solar metallicity (with some dispersion), while clusters farther away have  $[Fe/H] \sim -0.3$  dex (again with

some dispersion). Yong, Carney, & Teixeira de Almeida (2005) also find a discontinuity at 10 kpc in the radial distribution of the OC metallicity, and a *basement*  $[\text{Fe}/\text{H}] \simeq -0.5$  beyond that radius, but agree on the existence of a smooth gradient in the inner regions.

Open clusters are also good tracers of the Galaxy formation mechanism (Freeman & Bland-Hawthorn 2002), in particular of the thin disk. The old OCs may date the Galactic disk, as an alternative to White Dwarfs, which still give a wide range of values, depending on the adopted cooling models (Hansen & Liebert 2003). OCs do not offer only a value integrated on the whole disk, but give information on its different parts. If the discontinuity at 10–12 kpc described above is real, it may represent the limit of the original thick disk or the connection of OCs to the presence of accreted satellites (Frinchaboy et al. 2004, 2005; Bellazzini et al. 2004) or to the occurrence of major merger events (Yong et al. 2005). These possibilities are not mutually excluding, since the accretion-related clusters would be those in the outer part of the Galaxy, where the concept of “true” disk is fuzzy. As already noted by Friel (1995), old OCs may be the few survivors of the original ones that formed in the early Galaxy, or may be the product of later accretion or interaction with merging satellites.

Finally, OCs are excellent tests for stellar evolution theory, since they contain simple stellar populations (i.e. coeval stars with equal metallicity). Viable stellar evolution models must therefore reproduce the various features (morphology, number counts, color and luminosity functions) of their CMDs. Comparing theoretical and observational CMDs one can discriminate among different models and select the most realistic ones. The method of using synthetic CMDs to compare with observational data has proven to be much more informative and rewarding (Aparicio et al. 1990, Tosi et al. 1991, Skillman & Gallart 2002) than the classical isochrone fitting. These MonteCarlo simulations allow modeling of several additional parameters which dictate the distribution of points in the CMD, such as stochastic star formation (SF) processes, binary fraction, photometric spread, main-sequence (MS) thickness, data incompleteness and small number statistics. Consequently, the results not only provide a measure of the properties of

the cluster, but can also constrain the star formation history (SFH) and the initial mass function (IMF).

To try to improve our understanding in all these subjects it is crucial to build up a large sample of open clusters for which the age, distance and metallicity are all derived in the most precise and homogeneous way, to avoid spurious effects due to inhomogeneous treatments. For this reason, we are undertaking a long term project of accurate photometry and high-resolution spectroscopy to derive homogeneously ages, distances, reddening and element abundances in open clusters of various ages and Galactic locations, and eventually infer from them the evolution of the metallicity radial distribution. To this aim we need to collect at least 30 clusters, evenly distributed in age, metallicity and Galactocentric distance bins to allow for reliable derivation of possible trends (or lack thereof). Age, distance, and reddening are obtained deriving the CMDs from deep, accurate photometry and applying to them the synthetic CMD method described by Tosi et al. (1991). Accurate chemical abundances are obtained from high-resolution spectroscopy, applying to all clusters the same method of analysis and the same metallicity scale.

Here we describe the results obtained for the first half of the photometric sample. Spectroscopic abundances have been presented so far only for NGC 6819 (Bragaglia et al. 2001), NGC 2506, NGC 6134, IC 4651 (Carretta et al. 2004), and Cr 261 (Carretta et al. 2005) and will be the subject of fore-coming papers. This paper is organized as follows: the BOCCE photometric sample is described in Section 2 and the application of the synthetic CMD method in Section 3. The results obtained so far by BOCCE on age, distance and reddening of the examined clusters are summarized in Section 4, and discussed in Section 5 in terms of test for the stellar evolution models. Contaminating effects are examined in Section 6. A discussion of the mid-term evolution picture obtained from the currently assembled sample is provided in Section 7 and a summary in Section 8.

## 2. The photometric sample

Homogeneity is a fundamental requirement when using different data sets to make detailed

comparisons between observational data and models. To truly understand the variations in the different model parameters, one must minimize systematic errors. What is needed for the purposes described above is a large data set of open clusters, all observed with the same technique, analyzed with the same method, accurately and consistently calibrated in the same photometric system, and with well determined incompleteness factors and photometric errors. Our photometric sample is being built following these requirements.

Up to now we have acquired the photometry for more than 30 clusters, in some cases only in the B and V bands, in others also in the I band, and in a few cases also in U and additional bands. About half have been analyzed. All magnitudes have been calibrated to the Johnson-Cousins system, via observations of primary and secondary standard stars (Landolt 1992, Stetson 2000) properly selected to cover the color range of the cluster stars. All the data have been reduced with PSF fitting packages, particularly suitable for crowded fields photometry; we have used DAOPHOT (Stetson 1987, Davis 1994) in most cases, ROMAFOT (Buonanno et al. 1983) and PSFex (E. Bertin, priv. communication) in a few others. In all cases incompleteness factors and photometric errors have been determined with the help of extensive artificial star tests. All the details can be found in the original papers quoted in Table 1.

We have already published the results for 16 of these clusters<sup>1</sup>, which are listed in Table 1, together with the derived age, distance modulus, reddening, indicative metallicity and reference. For sake of homogeneity, all the listed quantities refer to the best cases obtained with synthetic CMDs (see next Sections) based on the Padova 1994 stellar models (Bressan et al. 1993, Fagotto et al. 1994), because these are the tracks which more often turned out to provide the best fit to the data. There are (a few) cases, however, where other stellar models were found to better reproduce the data (see next Sections and the papers quoted in Table 1 for details).

The metallicity indicated in Table 1 is that of

<sup>1</sup>All the published data are available in electronic form from the BDA (Base Des Amas) maintained by J.C. Mermilliod at <http://obswww.unige.ch/webda/webda.html>

the stellar models in better agreement with the data and cannot be taken as an accurate determination of the cluster elemental abundance, for which detailed spectroscopic analysis is necessary.

The clusters position in the Milky Way is shown in Fig. 1, where the four main spiral arms, as delineated by Georgelin & Georgelin (1976) and Taylor & Cordes (1993) are also displayed. The Sun is assumed to be located at 8 kpc from the Galactic center. The clusters already analyzed and published within the BOCCE photometric project are shown as filled dots, whilst those with ongoing analysis (listed in the first lines of Table 2) are represented by open circles; open triangles indicate the remaining clusters (also listed in Table 2) for which the photometric observations have already been performed.

Fig. 2 shows the empirical CMDs in the B-V color of the 16 clusters analyzed so far. They are plotted in order of decreasing age (see Table 1 and Section 4) rightwards from the top left panel. The corresponding CMDs in V-I for those clusters for which observations were performed also with the I filter are shown in Fig. 3.

The appearance of the CMDs clearly reflects both the Galactic location of the cluster and the telescope performances. Most clusters were observed with CCDs mounted at 1 meter-class telescopes (the 1.5m Danish and the 0.9 Dutch telescopes in La Silla, Chile, the 1.5 m Bologna Observatory one in Loiano, Italy, the Palomar 60 inches, USA). The exceptions can easily be recognized from the depth of the CMDs: NGC 6819, NGC 2099, NGC 2168 and NGC 2323 come from the CFHT open cluster survey (Kalirai et al. 2001a, 2001b, 2001c, Kalirai et al. 2003) and NGC 6939 from the Italian National telescope (TNG) on the Canary Islands, both being 4 meter-class telescopes. Finally, Be 22 and Be 29, while observed with a similar diameter telescope (the ESO New Technology Telescope on La Silla), are the farthest ones.

Field stars contamination appears in all CMDs. Its prominence depends of course on the sky area sampled (from the  $3.8 \times 3.8$  arcmin<sup>2</sup> of the Dutch telescope, to the  $42 \times 28$  arcmin<sup>2</sup> of the CFHT), but generally speaking, the clusters seen in the direction of the Galactic Anticenter (e.g. Be 21, Be 29 and Cr 110) are less affected by fore/background contamination than those lo-

cated towards the center (NGC 6253 and Cr 261). Furthermore, the contamination is lower in the third quadrant ( $180^\circ \leq l \leq 270^\circ$ ) than in the others, with nearby systems like NGC 2099, NGC 2168, NGC 2323, NGC 6819 and NGC 6939, with galactic longitude between  $\sim 74^\circ$  and  $\sim 221^\circ$ , as heavily contaminated as NGC 6253 and Cr 261. This depends partly on the proximity of populous spiral arms and partly on the presence of overdensities such as the disk warp and/or accreted satellites streams (see Discussion).

### 3. The application of the synthetic CMD method

Age, reddening and distances of all clusters have been derived applying the synthetic CMD method (Tosi et al. 1991) to the empirical CMDs. The best values of the parameters are found by selecting those providing synthetic CMDs with morphology, number of stars in the various evolutionary phases and luminosity functions (LFs) in better agreement with the empirical ones.

The synthetic CMDs are constructed via MonteCarlo extractions of mass - age pairs, according to an assumed IMF, SF law, and time interval of the SF activity. Each extracted synthetic star is placed in the CMD by suitable interpolations on the adopted stellar evolution tracks and adopting the Bessel, Castelli & Pletz (1998) tables for photometric conversion to the Johnson-Cousins photometric system. The absolute magnitude is converted to a *provisional* apparent magnitude by applying (arbitrary) reddening and distance modulus. The synthetic stars extracted for any *provisional* magnitude and photometric band are assigned the photometric error derived for the actual stars of the same apparent magnitude. Then, they are randomly retained or rejected on the basis of the incompleteness factors of the actual data, derived from extensive artificial star tests.

Once the number of objects populating the whole synthetic CMD (or portions of it) equals that of the observed one, the procedure is stopped, yielding the quantitative level of the SF rate consistent with the observational data for the prescribed IMF and SF law. To evaluate the goodness of the model predictions, we compare them with: the observational LFs, the overall morphology of the CMD, the stellar magnitude and color

distributions, the number of objects in particular phases (e.g., at the main sequence turnoff, MS TO, on the red giant branch, RGB, in the clump, etc.). A model can be considered satisfactory only if it reproduces all the features of the empirical CMDs and LFs. Given the uncertainties affecting both the photometry and the theoretical parameters (stellar evolution tracks included), the method cannot provide strictly unique results; however, it allows us to significantly reduce the range of acceptable parameters.

In this way we derive the age, reddening, and distance of the cluster, and indicate the metallicity of the stellar evolution models in better agreement with the data. In principle, the latter should be indicative of the cluster metallicity, but this depends significantly on some of the stellar model assumptions, such as opacities.

To estimate if, and how many, unresolved binary systems could be present in the cluster, the synthetic CMDs are computed either assuming that all the cluster stars are single objects or that an (arbitrary) fraction of them are members of binary systems with random mass ratio. The effect of unresolved binarism on the V magnitude and B-V color was first addressed by Maeder (1974) and more recently discussed by Hurley & Tout (1998). Here we have re-calculated the effect also on the V-I color using the Padova isochrones (Bertelli et al. 1994) and included it in the construction of the synthetic CMDs. Fig. 4 shows the adopted magnitude and color variations of MS objects of solar metallicity as a function of the mass ratio between the secondary and the primary component of the unresolved system. Again, the comparison of the resulting morphology and thickness of the synthetic MSs of each cluster with the observed ones allows us to derive information on its most likely fraction of binaries.

The advantage of the synthetic CMD method over the classical isochrone fitting to derive the clusters parameters is manifest: with the synthetic CMDs we take into account both the number of stars predicted by the adopted stellar tracks in each evolutionary phase (directly related to the stellar lifetimes in that phase) and the effects of the photometry (errors, incompleteness and image blend) on the morphology and spread of the various CMD sequences. This clearly provides a larger number of constraints and leads to a better

selection of the solution, if not to its uniqueness. For instance, an isochrone may appear to well fit the data, but then the corresponding distribution of the number of stars on the MS or at its TO is completely at odds with the empirical ones and the case must be rejected, or be given a lower ranking with respect to other models (see e.g. Kalirai & Tosi 2004). Moreover the blue and red edges of the MS distribution are important tools to quantify both the reddening (its mean value in the cluster direction and the existence of differential variations) and the presence of binary stars.

To test the effect of different input physics on the derived parameters, we have run the simulations of each cluster CMD with several different types of stellar evolutionary tracks. The adopted sets were chosen because they assume different prescriptions for the treatment of convection and range from no overshooting to rather high overshooting from convective regions. They are thus suitable to evaluate the intrinsic uncertainties still related to stellar evolution models. The three types of stellar models applied to all clusters are: the tracks of Ventura et al. (1998 and private communication, hereafter FST) with high ( $\eta = 0.03$ ), moderate ( $\eta = 0.02$ ) and no ( $\eta = 0.0$ ) overshooting; the tracks of the Padova group (Bressan et al 1993, Fagotto et al. 1994, hereafter BBC) with overshooting; and the tracks of the Frascati group (Dominguez et al. 1999, hereafter FRA) with no overshooting. The parameters of some of the clusters were also inferred, in the original papers, adopting the models computed by the Geneva group (first Maeder & Meynet 1989 and then Schaller et al. 1992 and Charbonnel et al. 1993) and by Vandenberg (1985).

Some of the clusters of our sample were analyzed and published before the advent of the stellar models currently available and their parameters were then derived with the same method but with different stellar tracks than clusters more recently studied. For such systems we have re-derived age, distance and reddening with the version of the BBC, FRA and FST models quoted above, so that all the results presented here have been obtained consistently. For sake of homogeneity, also the forthcoming analyses of the remaining clusters of the BOCCE project will be performed with the same sets of evolution tracks.

For those cases where the metallicities are not

well constrained, we allow different values in our comparisons. We consider as solar metallicity tracks those with  $Z=0.02$ , because they are the ones calibrated by their authors on the Sun, independently of the circumstance that nowadays the actual solar metallicity is suggested to be lower (see Asplund et al. 2004).

All models assume that the star formation activity has lasted 5 Myr (i.e., approximately an instantaneous burst, relative to the age of most of our studied clusters) and that the stars were formed following a single slope ( $x = 1.35$ ) Salpeter’s IMF over the whole mass range covered by the adopted tracks ( $0.6 - 100 M_{\odot}$ ): simplistic assumptions which however don’t affect our results, as demonstrated by several checks made assuming both different burst durations and IMFs.

#### 4. Ages, reddenings and distances from the CMDs

Table 3 lists age (in Gyr), intrinsic distance modulus and reddening derived for each cluster with the synthetic CMD method using the three different sets of stellar models described above. Each triplet of parameters refers to the best cases obtained with the BBC, FRA and FST models, for all the tested metallicities. The differences in the derived quantities provide a quantitative estimate of the intrinsic error attributable to the stellar evolution tracks.

Age is the parameter more affected by the theoretical uncertainties. Table 3 shows that there can be a factor up to 1.8 between ages derived with stellar models with or without overshooting from convective regions. It is well known that, for a given mass, stellar models taking overshooting into account have larger cores and are therefore brighter than models without it. This makes them appear as stars of slightly larger mass. Correspondingly, an object of given luminosity, in the framework of overshooting models has a lower mass (and therefore an older age) than with no overshooting models. Indeed, this is what we find for the majority of our studied clusters: the BBC and FST models provide ages older than the FRA models. The few exceptions to this rule are due to uncertainties on the best fitting model metallicity. If we do not consider the two oldest clusters Cr 261 and NGC 2243, for which the BBC models appear

to have problems (see next Section), the ages derived with the two types of overshooting models, BBC and FST, are in fairly good agreement with each other, since they differ at most by 20%.

Distance modulus and reddening appear to be much less affected by differences in the adopted stellar models, specially if we take into account that the available BBC, FRA and FST evolutionary tracks do not have the same nominal metallicities. In the range of interest for open clusters, the BBC models are available for metallicity  $Z = 0.004, 0.008, 0.02$  and  $0.05$ , the FRA models for  $Z = 0.001, 0.006, 0.01$  and  $0.02$ , and the FST models for  $Z = 0.006, 0.01, 0.02$  and  $0.03$ . Hence, only the CMDs of solar metallicity clusters could be compared with synthetic CMDs with the same metallicity for all types of tracks. This leads to an uncertainty in the derived reddening, which inevitably implies an uncertainty also in the distance modulus. On the other hand, all theoretical CMDs were transformed to the observational plane with the same photometric conversion tables (Bessel et al. 1998), instead of directly taking values given by each group, thus avoiding a further source of uncertainty.

Since the BBC models have turned out to better reproduce the overall features of the empirical CMDs of most of the clusters, we will adopt their resulting parameters as reference values. of age, intrinsic distance modulus  $(m-M)_0$  and reddening  $E(B-V)$  attributed to each cluster by the BBC stellar models from the application of the synthetic CMD method. The corresponding TO mass, model metallicity, distance  $d$  from the Sun and  $R$  from the Galactic center are also given. In a few cases (see next Section) the BBC evolution tracks were found to reproduce the clusters observed properties less satisfactorily than the FST or the FRA models. We have flagged with a colon the values in Table 1 corresponding to these cases, which are to be considered more uncertain. In the case of Cr 261, where the BBC models are likely to have failed, Table 1 shows the values inferred with the FST models. These values happen to be in agreement with those derived for Cr 261 by Carraro, Girardi & Chiosi (1999) via isochrone fitting with the new Padova stellar models (Girardi 2000).

Detailed comparison with other analyses of each cluster has been performed in the individual pa-

pers, and we do not repeat it here; we only mention the recent work on NGC 2243 by Anthony-Twarog, Atwell & Twarog (2005), since our original paper is old, and this study constitutes an important improvement on this cluster. As part of a larger project involving a series of key open and globular clusters, they used Strömgren photometry to derive the cluster parameters, arguing that intermediate-band photometry is able to reach more precise results than broad-band photometry, in particular for the metallicity. NGC 2243 was targeted because it is old, metal-poor, and just outside their proposed discontinuity near  $R_{GC} = 10$  kpc. They compare their results with Bonifazi et al.'s (1990), finding good agreement. This is still true with our present analysis, since they find as best values  $E(B-V) = 0.055$ ,  $[Fe/H] = -0.57$ , age = 3.8 Gyr, and apparent distance modulus 13.15 (see our updated parameters in Tables 1 and 3). They also rightly caution that, since the resulting estimates are tied to the adopted set of evolutionary tracks, it is safer to work on a relative scale to derive the properties of a sample of clusters. They also compare Be 29 to NGC 2243, again finding very good agreement with our determinations.

## 5. The cluster CMDs as stellar evolution tests

When the BOCCE project started many years ago (Romeo et al. 1989), the stellar evolution models available in the literature were still significantly affected by uncertainties in the treatment of the convective regions, in the adopted opacity tables, in the normalization to observed systems. The photometric conversions from the theoretical effective temperature – luminosity plane to the empirical color – magnitude plane were very uncertain too and often created ad hoc for each grid of stellar tracks, to let it reproduce the colors of observed objects. Moreover, most stellar models were computed for relatively small mass ranges, and it was therefore quite difficult to set up a homogeneous set of models covering the whole mass range of interest for open clusters (i.e. low and intermediate mass stars from  $0.6$  to  $8-10 M_{\odot}$ ). As a consequence, several of the adopted models were unable to properly reproduce all the CMD features of our observed clusters; first of all, the color of the red giant branch (RGB) and the morphology

of the MS TO.

The three types of stellar models (BBC, FRA and FST) adopted now are those that have proven most successful so far in reproducing the observational properties of the clusters. Nonetheless, none of them reproduces perfectly all the CMD features. The differences between predicted and observed features sometimes may be attributed to uncertainties in the data<sup>2</sup>, but in most cases they are the systematic consequence of the stellar model assumptions.

The FST models are very instructive in this respect because, for any given mass and metallicity, they provide three sets of tracks computed with the same assumptions except the amount of overshooting. By comparing the synthetic CMDs based on these three different amounts of overshooting ( $\eta=0.0$ , 0.02 and 0.03) with the empirical CMDs of our clusters we have found (Ventura et al. in preparation) that the models with overshooting are in much better agreement with the data than the models without it. Even for Cr 261, where core overshooting is in practice not effective because at that old age (6 Gyr with the FST models) MS stars have low mass and hence radiative cores, the  $\eta=0.02$  models are slightly better than the  $\eta=0.0$  ones. The only exception to this rule is NGC 2243 (which is also rather old, with an age of 4 Gyr with the BBC models and 2.9 with the FST ones), where all the FST models fail to provide a good fit to the empirical CMD, but the ones with  $\eta=0.0$  are less inconsistent than the others. In all the other cases with TO mass large enough to let the stellar core be convective (and overshooting be effective), the  $\eta=0.0$  models either do not populate correctly the clump and/or the TO region, or do not show the correct MS curvature.

It is interesting that, while the need of overshooting in the FST models is evident, it is almost impossible to systematically choose between  $\eta = 0.02$  or 0.03 from our data. For some clus-

ters we don't find significant differences in the agreement between empirical and synthetic CMDs switching from 0.02 to 0.03; for other clusters (Be 29, Cr 110, NGC 6939, Pismis 2) we find that the  $\eta = 0.02$  models better reproduce the data; but for yet other clusters (NGC 6819, NGC 2660, NGC 2168 and, possibly, NGC 2323) we find instead a better fit with the  $\eta = 0.03$  models. Looking at the values listed in Table 1, one might be tempted to find hints for an anti-correlation between the age of the cluster and the amount of overshooting, but we think that the sample is still too small, the uncertainties too large and the relation too loose to support this suggestion.

One intriguing aspect of stellar evolution models concerns the slope of the lower MS. Sometimes the photometry is not accurate enough to allow for a safe definition of the MS shape and curvature at faint magnitudes, but there are cases in which the photometry is reliable and the synthetic CMDs (and isochrones) do not reproduce them perfectly. This problem has been recently addressed by Grocholski & Sarajedini (2003), who presented a comparative study of isochrone fits to CMDs in the visual and infrared bands. They took five sets of theoretical models and compared them in the luminosity - temperature plane. They fit the observed CMDs of six open clusters, of various ages and metallicities, with the five sets of isochrones and found a variety of inconsistencies on the lower MS slope. Their results are somewhat affected by the fact that they use the isochrones as transformed from the theoretical plane (luminosity and temperature) to the observational one (magnitudes and colors) by each group of stellar modelers, i.e. following different prescriptions and introducing differential variations on the slope itself. In our case, this differential (and unknown) effect is absent, because we transform all the theoretical models with the same conversion tables. Still, we find the same kind of problems as described by Grocholski & Sarajedini: when the observed CMDs are deep enough, the fit to the lower main sequence is often (but intriguingly not always) bad. This happens in general around  $M_V \simeq 8$  for the visual colors, and is attributed by Grocholski & Sarajedini to some ingredient still missing in the model atmospheres for low mass stars. Indeed, this is likely to be at least one of the causes. For instance, the circumstance that most photometric conversions are ap-

<sup>2</sup>for instance, Twarog, Anthony-Twarog & De Lee 2003 have suggested the existence of a color term in the calibration of our photometry of NGC 6253, comparing it to other analyses of the same cluster; for this cluster there also appear to be quite large zero point shifts among available photometries. Anyway, the values they derive for this cluster are in reasonable agreement with our findings: metallicity definitely higher than solar, age between 2.5 and 3.5 Gyr, reddening 0.26 and apparent distance modulus between 11.6 and 12.2.

plied under gray atmosphere assumptions, which are likely not to be applicable to stars with  $M_V \geq 8$  is a probable source of inconsistency. Whatever the reason, there is no single set of tracks able to match all CMDs in all colors, at all ages, and for all metallicities. All of them behave quite well in some cases, but not in others.

With our sample of OCs, we have found that the FST models in some cases predict too steep MS slopes at the lower masses, in spite of being usually able to reproduce the observed features of the upper MS and TO better than other models. In fact, we have found that, while reproducing the colors and magnitudes of the upper MS, the faint end of the FST synthetic MS is too blue (and bluer than that of the BBC and FRA models) for NGC 2243, NGC 6819 and NGC 6939. In a few cases (e.g. NGC 2660) the FST models overpredict the number of faint MS objects more than other stellar tracks (i.e. more than attributable to evaporation effects).

The FRA models are the only ones able to well reproduce the MS curvature of NGC 6819 and Pismis 2, and fit perfectly the older cluster Cr 261. On the other hand, they often overpopulate the post-MS phases and present a too hooked TO morphology at young and intermediate ages (see e.g. NGC 2099, NGC 2168, NGC 2323 and NGC 6819 in Kalirai & Tosi 2004), which make them less viable than other tracks for clusters younger than  $\sim 2$  Gyr.

The BBC tracks turn out to be those in overall better agreement with the observed CMDs. In other words, they steadily provide a good fit to the data of (almost) any age and metallicity, even if they may appear to reproduce detailed features, such as MS gaps and bumps, TO shape, clump numbers, in a less strikingly good manner than other models. The only case where the BBC tracks have not led to a convincing result is Cr 261. For that cluster we (Gozzoli et al. 1996) found an age of 11 Gyr with the BBC models, much older than with tracks without overshooting, as if overshooting were strongly active in the cluster stars, despite their low mass (the TO mass is about  $1.1 M_\odot$ ) which implies a radiative and not a convective core. We have reexamined its case, with the FRA and FST models, not available at the time of that study, and found a very good fit to the observational CMD for an age of 5 Gyr with the

FRA models or 6 Gyr with the FST models (independently of the adopted amount of overshooting, as expected, since overshooting should not be active in low mass stars). The problem with the BBC tracks (and isochrones, Bertelli et al. 1994) is that at ages of 6 to 9 Gyr they show a hooked TO, which is usually appropriate for younger systems and does not reproduce the smooth tighter morphology of the TO of Cr 261. At older ages, the BBC TOs recover the proper shape, but then the clump luminosity becomes excessively bright for Cr 261. It is interesting to note that the new Padova isochrones (Girardi 2000) present TO shapes much more similar to those of the FST and FRA models (and of Cr 261, see also Carraro et al. 1999 and their fig.1) at these ages. We thus feel that the BBC stellar models might have had some problems in the TO evolutionary phases of low mass stars, subsequently overcome in more recent computations.

## 6. Field contamination, reddening and binary systems

A safe derivation of cluster age, reddening and distance from CMDs requires not only reliable photometry, with accurate calibration, but also a careful analysis of the back/foreground contamination and as much as possible information on the actual cluster membership of the measured stars. In fact, the shape and the luminosity of the corner stones for the parameters derivation (upper MS, TO and clump) may be significantly altered by the presence of line of sight intruders. Unfortunately, studies of radial velocities or proper motions of the individual stars are available only for a few open clusters and often the only means to estimate cluster membership is by comparison with nearby blank fields. De-contamination is even more crucial if one aims at deriving also the cluster initial mass function or the star formation rate. We thus emphasize the importance of acquiring the photometry of appropriate blank fields, even if this requires additional observing time and a careful choice of the field position. The case of the beautiful CMDs from the CFHT open cluster survey (Kalirai et al. 2001a, 2001b, 2001c, Kalirai et al. 2003) is illustrative. Despite the large field of view of the CFH12K mosaic camera ( $42' \times 28'$ ) Kalirai & Tosi (2004) have found that in the case of NGC 2168 and NGC 2323 many cluster members are

still present even at the edges of the observed field: the lack of observations of an external field prevents any reliable estimate of the back/foreground contamination.

Open clusters are affected by dynamical friction with the Galactic disk and by stellar evaporation, so that stars initially members can be found at rather large distances from the cluster center. An example is given e.g. by Be 22 (Di Fabrizio et al. 2005, see figs. 4 and 5), for which we acquired a comparison field at a distance of 30 arcmin from the cluster center that still shows a main sequence similar to that of the cluster. Since this MS is not present in the Galactic synthetic models of the field disk population by Robin et al. (2003), its most likely interpretation is that cluster members are present even at such large distance. This makes it additionally uncertain to infer membership by statistically subtracting the objects found in adjacent fields. For this reason, we have generally restricted our derivation of the cluster parameters to the CMDs of their most central regions, where field contamination is smaller. The synthetic CMD method, by providing the theoretical number of stars in all evolutionary phases, allows to easily individuate the clusters where evaporation is more likely to have occurred. Clusters whose fainter main sequences are systematically underpopulated with respect to those of the corresponding synthetic CMDs are robust candidates for evaporation, once the reliability of the incompleteness factors is guaranteed by extensive and appropriate artificial star tests. In our sample, we have found that NGC 6253, NGC 6819, Be 29 and Cr 261 have faint MSs systematically less populated than the corresponding ones predicted by all the stellar models. We thus consider these clusters as having suffered significant evaporation of low mass stars during their life. These four systems are among the oldest ones of the provisional BOCCE sample and have had more time than the others to loose an appreciable fraction of their stars. It is interesting to notice, though, that Be21 and NGC 2243, which are also older than 2 Gyr, do not show evidence of evaporation. NGC 2243 is by far the OC more distant from the Galactic plane in our entire sample, and this may explain it; no simple explanation is available for Be 21.

We have not generally tried to determine the extension of our OCs, partly because it was out-

side the main goal of our project, partly because our field of view is often so small as to make it impossible. Only for the farthest clusters (Be 29, Be 22 - already discussed in Di Fabrizio et al. 2005 - Be 21) or for the few observed with a larger field of view (NGC 6939, Cr 261) the exercise is worthwhile. The radial extent of the 4 OCs observed with the CFHT has already been determined (Kalirai et al. 2001b,c; 2003): NGC 6819 has a radius of 9.5 arcmin, NGC 2099 of 13.9 arcmin, while the determinations for NGC 2323 (about 15 arcmin) and NGC 2168 (more than 20 arcmin) are more uncertain, since the clusters seem to fill the entire field of view. We computed the radial star density distribution for Be 29, Be 21, NGC 6939, and Cr 261. We show in Fig. 5 the projected density distribution (in annuli 10 or 20 arcsec wide) for the 4 OCs, giving distance from the centers both in arcsec and in parsec. The only one for which a flattening of the distribution is indisputable, so we can determine where the cluster disappears, is Be 29 (with a radius less than about 3 arcmin, in good agreement with the value in the Dias et al. 2002 catalogue). The distribution for Be 21 is still decreasing at our field's edge, and the same seems to be the case for NGC 6939, where we chose only stars brighter than  $V = 22$ , to avoid problems with an excessive field stars fraction and incompleteness of our photometry. Finally, Cr 261 (where we considered only stars brighter than  $V = 20$ ) seems to constitute a small fraction of the observed field, as already found by Gozzoli et al. (1996).

As many disk objects, our clusters are generally affected by significant reddening. However, only few of them clearly suffer also from differential reddening. The synthetic CMD method, by distributing the stars in the CMD according not only to the evolutionary phase, but also to photometric errors and fractions of presumed binary systems, allows one to quantify differential reddening more safely than with simple isochrone fitting. A varying reddening widens the whole MS by a given amount  $\Delta E(B-V)$ , while unresolved binaries produce a secondary sequence redder/brighter than the single stars MS, intersecting it above the TO region. In practice, differential reddening and binarism are distinguishable from each other because the former implies a smooth spread of the MS from the TO down to its faintest portions,

whilst unresolved binaries, even if distributed with random mass ratios, imply a split of the MS and the appearance of a bright appendix (up to 0.75 mag brighter, corresponding to equal mass binaries) on top of the TO. Based on these arguments, we have found that Be 21 and Pismis 2 are the only systems of our current sample clearly affected by differential reddening ( $0.04 \lesssim \Delta E(B-V) \lesssim 0.1$ ). Work in progress (Bragaglia et al. 2005, in preparation) on the photometric data and the spectra of three stars in NGC 3960 indicate also for this cluster some differential reddening, confirming the finding by Prisinzano et al. (2004).

All the clusters, instead, seem to contain unresolved binary systems, with estimated percentages varying between 15% and 60%.

NGC 2099, NGC 2168, NGC 2323 and NGC 6819, in addition to the binary sequence, show MS widths larger than attributable to the measured photometric errors (Kalirai & Tosi 2004). This could be due to a differential reddening of the order of 0.01 mag and/or to internal metallicity spread. However, in these cases we rather tend to ascribe the MS width to the difficulty in calibrating the different CFH12K CCD chips (McCracken, private communication).

## 7. Discussion and preliminary results

With the derived reddening and distance modulus, the observational CMDs can be plotted as absolute magnitude vs intrinsic color (Fig. 6). In this reference frame, the TO brightness obviously anticorrelates with the cluster age, while the clump luminosity at first sight is roughly constant, although actually inversely proportional to the chemical abundance. At first order approximation, the magnitude difference,  $\Delta V$ , between TO and clump is thus an age indicator. A safe use of this indicator requires a careful and homogeneous definition of the reference TO and clump points, which are affected by photometric uncertainties, including blending of unresolved stars, small number statistics, and back/foreground contamination. In practice, the identification of the reference points differ from one author to the other. For instance, Twarog & Anthony-Twarog (1989) define the morphological age ratio (MAR), reddening independent and almost metallicity independent, as the magnitude difference between

the brightest TO point and the clump, divided by the color difference between the RGB color at the clump luminosity and the bluest TO point. Janes & Phelps (1994) adopt as morphological age index (MAI) the magnitude distance from the red clump of the inflection point between the TO and the base of the RGB, as did more recently Salaris, Weiss & Percival (2004). Carraro & Chiosi (1994) assume that the reference TO luminosity is 0.25 mag fainter than observed in the CMD, because of the possible presence of unresolved binaries which brighten the apparent TO.

The oldest cluster of our provisional sample is Cr 261, whose age has been conservatively estimated with the FST models, due to the problems with the BBC tracks discussed in the previous Section. Its  $\Delta V$  is 2.6. The next older systems are in the interval 4 – 3 Gyr (Be 29, NGC 2243 and NGC 6253), with  $2 \lesssim \Delta V \lesssim 2.5$ . The clusters younger than 1 Gyr (NGC 7790, NGC 2323, NGC 2168, NGC 2099 and NGC 2660) all have  $\Delta V$  between 0.2 and 0.5 and both the TO and the clump are much more difficult to individuate, because of the small number of cluster members in these evolutionary phases.

Fig. 7(a) shows that  $\Delta V$  seems well correlated with the cluster age derived with our method, and the line represents a preliminary calibration of this relation. Although it appears as a very reasonable approximation, we will not make use of it in its present form: these 16 clusters are still too few to give a reliable calibration between  $\Delta V$  and age because they were not chosen for this purpose, and do not sample the entire relevant age range (see e.g. Salaris et al. 2004 for a discussion on their choice of calibrating clusters). In particular, we miss the oldest OCs, and a definitive calibration will have to wait until at least Be 32 (age  $\sim 6$  Gyr), Be 17 and NGC 6791 (both with age  $\sim 10$  Gyr) will be properly analyzed (for the first two clusters work is already in progress). Furthermore, precise metallicities are, or will soon be, available for (most of) the clusters in our sample, either from our work (e.g., Cr 261: Carretta et al. 2005; Be 17, Be 32, and NGC 6791 for which we have acquired high resolution spectra) or from the literature (e.g., Be 29: Carraro et al. 2004; Be 17: Friel, Jacobson, & Pilachowsky 2005). This is important to test the metallicity dependence of the  $\Delta V$  - age relation. As explained e.g., in Salaris

et al. (2004), isochrones of different metallicity have different values of  $\Delta V$  for the same age, since the luminosities of the TO and the RC depend in different ways on age and metal abundance. In particular, lower metallicities should show a larger  $\Delta V$  for the same age. In our case the situation is confused: we have three clusters with the same  $\Delta V$  but the age difference does not seem to correlate univocally with the metallicity. Larger samples, and better defined metal abundances, have to be employed to decide whether and how this influences the calibration of this useful relation.

From the derived distance moduli and reddenings we calculated the Galactic position of the clusters, used to draw Fig. 1. NGC 6253 is the system closer to the Galactic center and Be 29 the farthest one. To better visualize the relations (or lack thereof) between age, Galactocentric distance and metallicity, we have plotted these quantities in Fig. 7(b,c,d). We recall, however, that the metallicity derived here is that of the BBC models in better agreement with the cluster CMDs and should not be taken as a precise measure of the actual cluster metallicity. To safely determine the cluster chemical abundances accurate spectroscopic studies are necessary. Bearing this caveat in mind, Fig. 7 shows that the only relation clearly existing between the derived quantities is the metallicity dependence on Galactocentric distance [Fig. 7(d)], while there is no apparent relation between age and metallicity. If we don't take the outermost point into account, we cannot exclude a dependence of the cluster age on Galactocentric distance; however, the spread in the second panel from top is quite large and we need a much larger sample to better pin point this relation (or lack thereof). Similar results were already found and discussed by Janes & Phelps (1994) and Phelps, Janes & Montgomery (1994), with a much larger sample of clusters, but more uncertain parameter derivation. Carraro et al. (1998) argued that, after correcting the cluster metallicities for the radial gradient effect, their clusters do show an age-metallicity relation similar to that inferred from field stars in the solar neighborhood. However, their corrected age-metallicity distribution (their fig.8) looks as scattered as ours [Fig. 7(c)], with no apparent trend. Yong et al. (2005) find no correlation between age and metallicity in their compiled sample of OCs.

Do we really see a radial abundance gradient in the Galactic disk? Fig. 8 shows our data<sup>3</sup> compared to the homogeneous samples by Friel et al. (2002) and Twarog et al. (1997). As already mentioned in the Introduction, the latter, on the basis of their re-homogenization of OC metallicities, presented the hypothesis that the true original metallicity distribution in the Galactic disk is not described by a simple linear gradient, but is a step distribution, with clusters inside  $R_{GC} = 10$  kpc with solar metallicity (and a dispersion of  $\pm 0.1$  dex) and those outside with a metallicity 0.3 dex lower, with a similar dispersion (see Fig. 8, lower panel, which uses data from Twarog et al. 1997). They discussed at length the different metallicity distributions of clusters and field stars and suggested that the differences are mostly due to the much larger orbital diffusions of individual stars. Corder and Twarog (2001) modeled the evolution both of a linear and a step distribution in metallicity for field stars and open clusters, and found that a step distribution does appear as a linear gradient if orbital diffusion is the dominant factor, like for field stars. For open clusters, instead, evaporation dominates, allowing to preserve the original discontinuity. The large sample in Twarog et al. (1997) was dominated by youngish clusters (age  $< 2$  Gyr) and the original step distribution (which still survives) could be recognized. Corder & Twarog (2001) attribute the linear gradient found e.g. by Friel (1995) to the too small radial baseline, with most of clusters near the discontinuity (in the range 8-12 kpc). They suggest to concentrate efforts on objects much nearer to, and farther from, the Galactic center to avoid this effect.

Our clusters cannot prove or disprove this description yet: we still have too few objects at any given  $R_{GC}$ , we are biased towards large ages, and our homogeneous metallicities come from the evolutionary tracks. Our inner clusters have predominantly solar metallicity, and of the three OCs definitely outside the 10 kpc limit (remember that

<sup>3</sup>We have translated our photometrically determined  $Z$  values to the corresponding  $[Fe/H]$  values, for more immediate comparison with the two other samples. We also plot here the available  $[Fe/H]$ 's based on high-resolution spectroscopy, that are not (yet) on a thoroughly homogeneous scale, since three of them come from literature (see Table 4).

we are using  $R_{GC,\odot} = 8$  kpc), two have  $[Fe/H] \sim -0.4$  (from spectroscopic analyses) and one has  $Z=Z_{\odot}$  (Be 22, from the synthetic CMDs method; see however Villanova et al. 2005). More clusters at these Galactocentric distances should be studied in detail and a more precise abundance determination has to be performed. We list in Table 4 the presently available metallicities based on high resolution studies; 5 were determined by our group and 3 come from literature, so they are not yet on a homogeneous scale.

In any case, a simple single-slope gradient cannot be the best answer: our present sample contains the very distant cluster Be 29, which has abundances higher than what is given by a linear extrapolation of the gradient found for OCs nearer to the Galactic center (see Fig. 8, upper and middle panels). The same is true for Saurer A with  $R_{GC} \simeq 19$  kpc and  $[Fe/H] = -0.38$  (Frinchaboy & Phelps 2002, Carraro et al. 2004). The fact that inner and outer disk clusters do not seem to follow the same radial abundance distribution was already noticed by Carraro et al. (2004), who proposed two alternatives: a different chemical evolution history for the outer disk (e.g. Chiappini et al. 2001) or an extragalactic origin of Be 29 and Saurer A<sup>4</sup>. Yong et al. (2005), combining literature data with high-resolution spectral analysis of M67 and five outer disk OC's (Be 20, Be 21, Be 29, Be 31, and NGC 2141), also argue that open clusters show a linear metallicity gradient in the regions within 10 – 12 kpc from the Galactic center, but have a roughly constant metal content from there outwards. Their favored interpretation is that the outer clusters are the result of star formation triggered by a major merger event. Direct capture of alien clusters from accreted dwarf galaxies seems unlikely, since the relatively high  $[\alpha/Fe]$  ratios measured in their five clusters are not consistent with those measured in nearby dwarf galaxies (Venn et al. 2004 and references therein).

Crane et al. (2003) and Frinchaboy et al. (2004) connected several open and globular clusters to the Galactic Anticenter Stellar Structure (GASS; e.g., Newberg et al. 2002, also called Ring, or Monoceros Ring). Bellazzini et al. (2004) proposed a few open clusters to be linked to the Canis

Major dwarf (CMa) that may (Martin et al. 2004), or may not (Momany et al. 2004) be a real accreted satellite, and that may perhaps be (Martin et al. 2005), or not be (Peñarrubia et al. 2005) the cause of the GASS. The two groups have different approaches. Crane et al. (2003) and Frinchaboy et al. (2004, 2005) use position and radial velocity of galactic clusters to see if they lie along the GASS, while Bellazzini et al. (2004) look at the CMDs of clusters at about the same position and distance of the CMa system, and compare the cluster and surrounding field population with the CMa one.

A few clusters in our sample have been considered to be associated to CMa or to the GASS, on the basis of their CMD and/or radial velocity. For To 2 (Frinchaboy et al. 2004, 2005; Bellazzini et al. 2004) and Be 29 (Frinchaboy et al. 2004, 2005) there is a strong positive indication. Be 22, on the contrary, has been discarded both by our work (Di Fabrizio et al. 2005) on the basis of a comparison between the CMDs of the central and control fields and that of the CMa overdensity, and by Frinchaboy et al. (2005) because its radial velocity does not fit the GASS longitude-velocity trend (this remains true also considering the slightly lower radial velocity determined by Villanova et al. 2005). In the case of Be 29 we have tried to apply both methods to our data (Tosi et al. 2004): the galactic coordinates and radial velocity (measured by Bragaglia, Held & Tosi 2005, and by Carraro et al. 2004) put it right in the GASS (see also fig. 1 in Frinchaboy et al. 2005), but our field of view is too small to give a definite answer about similarities between Be 29 and CMa or dissimilarities with the expected galactic disk population based on Robin's et al. (2003) model.

All the other clusters of our present sample are too close to the Galactic center and/or have radial velocities that exclude the association with the Ring (see Table 4). We have anyway checked that no unaccounted component was present in our CMDs by comparison with the ones produced by the Robin et al. (2003) Galactic model, in each direction, for the appropriate field of view, taking into account the magnitude limit and completeness factor of our photometry. This test - negative in all cases - is of course truly significative only for the cases where the field of view was large enough as to sample even a marginal contaminating population.

<sup>4</sup>They associated Be 29 to the Monoceros Ring, but not Saurer A, at variance with Frinchaboy et al. (2004, 2005)

The importance of understanding the true origin of outer disk open clusters is clear. For instance, Be 29, the farthest known OC, is fundamental to study the metallicity gradient, if its origin is fully Galactic. On the other hand, if Be 29 is demonstrated to come from another galaxy with a different chemical history, the interest would be shifted towards understanding which signatures (if any) characterize the accreted populations, in order to identify and separate them in the Galactic disk. The Sagittarius dwarf appear to display chemical peculiarities (Bonifacio et al. 2004, McWilliam & Smecker-Hane 2005), and recently Sbordone et al. (2005) claimed that at least one star, possible member of the CMa, shows chemical signatures (abundance ratios of  $\alpha$ -elements, Cu, and heavy neutron capture elements like La, Ce and Nd) more appropriate for Local Group dwarf galaxies than for the Milky Way.

Both To 2 and Be 29 have been studied with high resolution spectroscopy; do they show similar signatures? In To 2, Brown et al. (1996) measured  $\alpha$ -elements and La. For the latter they find  $[\text{La}/\text{Fe}] = 0.5$ ; for the former  $[\alpha/\text{Fe}] = +0.07$  dex, a value in perfect agreement with many other old OCs (see e.g. Friel et al. 2003) but unlikely for dwarf galaxies, where it tends to be under solar (Venn et al. 2004). Carraro et al. (2004) did not measure heavy elements in their two Be 29 targets, but have  $\alpha$ -elements, that are said to be enhanced with respect to the solar values, at variance e.g. with NGC 2243, which has similar overall metallicity ( $[\text{Fe}/\text{H}]$  around  $-0.4$  dex). However, from the values published in their tab. 5,  $[\alpha/\text{Fe}]$  is about 0.08 dex, exactly the average found for NGC 2243 by Gratton & Contarini (1994), and again a common value for old open clusters.

## 8. Summary

To summarize the mid-term results of the photometric BOCCE project:

- We confirm the tight relation between cluster age and magnitude difference between MS TO and clump luminosity levels, but caution against its application to young objects, where small number statistics and field contamination may make the determination of the two luminosity levels too uncertain.

- We confirm the anticorrelation between metallicity and distance from the Galactic center. We don't find evidence of discontinuities around 10-12 kpc from the center, but our sample is still too small to distinguish between a smooth gradient and alternative distributions.
- We find definitely no correlation between cluster age and metallicity.
- We cannot completely exclude an age-Galactocentric distance relation in the inner 10-15 kpc.

Most of the oldest clusters of the sample (NGC 6253, NGC 6819, Be 29 and Cr 261) show clear evidence of evaporation of their lowest mass stars. Almost all our clusters appear to have stars (still bound members ?) with the same CMD morphology at quite large cluster radii. This circumstance makes it crucial to always observe control fields at appropriate distances from the cluster center.

We emphasize the importance of deriving the cluster parameters with more than one set of stellar evolution models and with the same photometric conversion tables to allow for a direct comparison of the different model predictions and for a correct evaluation of the theoretical uncertainties on the results. We have not found a set of evolutionary tracks able to reproduce in detail all the observed features of old and young, metal rich and metal poor clusters. However, all the three evolution sets adopted in this project perform quite well in the comparison with the observational CMDs and LFs of the examined clusters, with the BBC models being often found in better agreement with the data. Overshooting from convective regions appears to provide a better fit to the observed properties of stars in the various evolutionary phases, with some hints that it might be more conspicuous in younger systems. As found also by Grocholski & Sarajedini (2003), the CMD region more difficult to reproduce is the lower MS, where stellar models often fail to provide the appropriate shape or slope. We agree with them that the most likely explanation for this problem is the inadequacy of the adopted photometric conversions, based on gray atmospheric models, for the lowest mass stars.

These results are by no means conclusive, since we need to at least double our clusters sample to get enough statistics in each age and distance bin. Moreover, we need to derive accurate chemical abundances from high resolution spectra for a through interpretation of the apparent metallicity distributions. Nonetheless, we consider it useful to illustrate the importance of a homogeneous approach in the derivation of the global cluster properties and emphasize the need of further accurate studies of these Galactic objects which can tell us so much more than others on the Milky Way evolution.

We thank all the colleagues who have collaborated so far to the photometric part of the BOCCE project: Gloria Andreuzzi, Lino Bonifazi, Antonio Carusillo, Luca Di Fabrizio, Flavio Fusi Pecci, Enrico Gozzoli, Don Hamilton, Gianni Marconi, Ulisse Munari, Luigi Pulone, Giuseppina Romeo, Stefano Sandrelli and Gianni Tessicini. Jason Kalirai has also participated, providing the beautiful photometric data from the CFHT. We also appreciate private communications on two clusters from Elena Pancino and interesting discussions with Eileen Friel, who also kindly shared information in advance of publication. We also wish to thank the anonymous referee for the very encouraging report. We have made extensive use of the BDA, a very useful tool for which we are sincerely grateful to J.-C. Mermilliod. This project has been partially supported by MIUR, under the Cofin project 2003029437.

<sup>a</sup>Cr 261 is the only cluster of the Table for which the listed parameters are derived with the FST models rather than with the BBC ones. See text for details.

<sup>b</sup>Colons indicate more uncertain values, resulting from non satisfactory synthetic CMDs

TABLE 4

HELIOCENTRIC RADIAL VELOCITIES AND METALLICITIES FROM HIGH RESOLUTION STUDIES FOR THE PRESENT SAMPLE. REFERENCES ARE FOR BOTH RV AND  $[\text{Fe}/\text{H}]$  WHEN THE LATTER IS AVAILABLE. WE ALSO GIVE FOR COMPARISON  $Z$ , THE PHOTOMETRIC METALLICITY, TAKEN FROM TABLE 1;  $Z = 0.004$ ,  $0.006$ ,  $0.02$ ,  $0.05$  MEAN  $[\text{Fe}/\text{H}] \sim -0.7$ ,  $-0.5$ ,  $0.0$ ,  $+0.4$ , RESPECTIVELY

| Cluster               | RV<br>$\text{kms}^{-1}$ | $[\text{Fe}/\text{H}]$ | $Z$   | Ref |
|-----------------------|-------------------------|------------------------|-------|-----|
| Cr 261 <sup>a</sup>   | −25.9                   | −0.03                  | 0.020 | 1   |
| NGC 2243 <sup>a</sup> | +61.0                   | −0.48                  | 0.006 | 2   |
| Be 29                 | +24.6                   | −0.44                  | 0.004 | 3   |
| NGC 6253 <sup>a</sup> | −26.2                   | +0.36                  | 0.050 | 4   |
| Be 22                 | +95.3                   | −0.32                  | 0.020 | 5   |
| Be 21                 | +12.4                   | −0.54                  | 0.004 | 6   |
| NGC 6819 <sup>a</sup> | +4.2                    | +0.09                  | 0.020 | 7   |
| NGC 2506 <sup>a</sup> | +83.7                   | −0.20                  | 0.020 | 8   |
| Cr 110                | +40.0                   |                        |       | 9   |
| NGC 6939              | −19.0                   |                        |       | 10  |
| Pismis 2              | +49.8                   |                        |       | 11  |
| NGC 2660              | +21.2                   |                        |       | 12  |
| NGC 2099              | +7.7                    |                        |       | 13  |
| NGC 2168              | −8.0                    |                        |       | 14  |
| NGC 2323              | +9.0                    |                        |       | 15  |
| NGC 7790              | −78.0                   |                        |       | 16  |

<sup>a</sup> $[\text{Fe}/\text{H}]$  values measured by our group

(2001); 8: Carretta et al. (2004); 9: E. Pancino, priv.comm., preliminary; 10: Milone (1994); 11: Friel et al. (2002); 12: propr.data, preliminary; 13: Mermilliod et al. (1996); 14: Barrado y Navascues et al. (2001); 15: Harris (1976); 16: Gorynya et al. (1992)

Fig. 1.— Positions on the Galactic plane of the OCs in our sample; filled circles represent published OCs, open circles work in progress, and open triangles the remaining clusters. We show the positions of the Sun and the Galactic center, and a sketch of the spiral arms (respectively: 1 = Norma, 2 = Scutum-Crux, 3 = Sagittarius-Carina, 4 = Perseus)

Fig. 2.— V, B-V CMDs of the 16 OCs, shown in decreasing age order.

Fig. 3.— V, V-I CMDs of the 10 OCs with I data, shown in decreasing age order.

Fig. 4.— Effect of unresolved binaries on the apparent magnitude and color as a function of the mass ratio between the secondary and primary component of the system and for various masses of the primary star. Line symbols refer to primaries of the following initial mass: 26 (solid), 14 (dotted), 4.5 (short-dashed), 2.55 (long-dashed), 1.76 (short-dash-dotted), 1.14 (long-dash-dotted), 0.95  $M_\odot$  (short-dash-long-dashed). The shown variations refer to solar metallicity MS stars from the Padova isochrones (Bertelli et al. 1994).

Fig. 5.— Projected density distribution for Be 29, Be 21, (both computed with a bin 10 arcsec wide), NGC 6939, and Cr 261 (both with bin = 20 arcsec).

Fig. 6.— CMDs for the 16 OCs in absolute magnitude and intrinsic color.

Fig. 7.— For the clusters listed in Table 1 we show the distributions of: (a) age vs magnitude difference between TO and clump (filled circles, open circles, filled triangle indicate  $Z$  solar, sub-solar or supersolar, respectively), with a line representing our preliminary relation (see text); (b) age vs Galactocentric distance (same symbols); (c) age vs model metallicity; (d) model metallicity vs Galactocentric distance.

Fig. 8.— Galactocentric metallicity distribution. Here we show  $[\text{Fe}/\text{H}]$  instead of  $Z$ , but on the right side of each figure we indicate the level of a few representative  $Z$  values for immediate comparison. Top panel: our sample, where filled squares are photometric metallicities, and filled dots are  $[\text{Fe}/\text{H}]$  based on high resolution spectroscopy while open squares are the corresponding photometric values. Middle panel: Friel et al.'s (2002) data, with the gradient based on their data, which has a slope of  $-0.059 \text{ dex kpc}^{-1}$ . Bottom panel: Twarog et al.'s (1997) data, that they interpret as a step distribution, with the two metallicity levels indicated by the dashed lines:  $[\text{Fe}/\text{H}] = 0$  for  $R < 10 \text{ kpc}$ , and  $-0.30$  for  $R > 10 \text{ kpc}$ .
